Figure 1. Acid phosphatase activity in NSF and SF calli of normal and variant callus cultures of Nicotiana tabacum L. cv. White Burley.

appearance. In normal callus where shoots appeared on the 10th day, the activity was at its peak on the 8th day. Similarly in variant callus, peak activity appeared on the 10th day while shoots were visible on the 12th day.

Comparison of the pattern presented in figure 1 suggests that the normal callus cultures under NSF conditions had higher activity than under SF conditions. On the contrary, variant callus exhibited greater activity under SF conditions than under NSF conditions. But the pattern of activity in the shoot-forming normal and variant callus remains the same which agrees with an earlier report. According to these, shoot regeneration was obtained in different media in the same variety in 25 days. The peak acid phosphatase activity appeared on the 13th day before the visible organogenesis. Using different media under which the time schedule for shoot formation was altered, a similar pattern is observed in our study (i.e. peak of acid phosphatase activity preceeded the visible organogenesis). This indicates that under different sets of conditions, shoot formation follows a similar pattern and the biochemical events leading to it are also similar.

**CHAETOMIUM SHEATH BLOTCH: A NEW DISEASE OF RICE**

S. R. DAS, P. K. BARIK, K. C. MOHANTY and N. N. MOHANTY

*Plant Pathology Division*, *Orissa University of Agriculture and Technology*, *Bhubaneswar* 751 003, *India*.

**Chaetomiun** sheath blotch, a new rice disease was identified on low land rice variety ‘Gopalbhog’ during September 1985 from the Balugan area of Orissa. The disease initiated on the leaf sheath as large oval to elliptical blotches which were brown to dark brown in colour (figure 1). The margins of individual blotches were deep brown to amber in colour with greyish white centre. The blotch measured 23–30 mm in length and 6–8 mm in breadth. In an affected sheath 1–3 blotches were observed. Sometimes one or more such spots coalesced to form large irregular necrotic blotches. The corresponding leaf blades of affected sheaths became pale, chlorotic and often withered. Symptoms were quite similar to that of sheath blotch incited by *Pyrenochaeta oryzae*.

Figure 1. Symptom showing Chaetomiun sheath blotch on rice leaf sheath (Gopalbhog).
The infected leaf sheaths were isolated on PDA and the fungus isolated in pure culture. Pathogenicity was tested by spraying heavy spore suspension and the mycelial fragments on wounded and unwounded surface of leaf sheaths of 8-week-old potted rice plants (Gopalbhog).

Perithecia of the fungus were subglobose, ostiolate, brown, base slightly pointed and measured 30.6–102 × 20.4–68 μ, terminal hairs were stiff, septate, unbranched. Asci were cylindrical, 8-spored, ascospores single-celled, lemon-shaped, brown and measured 3.4–6.8 × 3.4–6.8 μ. The fungus was identified as Chaetomium brasilense Batista and Pontval. The genus Chaetomium is considered to be a saprophytic one. But recently some species of the fungus have been reported as pathogenic causing leaf spots on different plants1,3,4. Available literature suggests that this is the first report of pathogenic behaviour of C. brasilense causing sheath blotch of rice from India and elsewhere. The specimen has been deposited at the Commonwealth Mycological Institute, Kew, Surrey, England (IMI No. 304884).

The authors are grateful to Dr P. F. Cannon of CMI, England for help in speciation of the fungus.

17 August 1987; Revised 10 December 1987
